Abstract. We prove some theorems about self-avoiding walks attached to an impenetrable surface (*i.e.* positive walks) and subject to a force. Specifically we show the force dependence of the free energy is identical when the force is applied at the last vertex or at the top (confining) plane. We discuss the relevance of this result to numerical results and to a recent result about convergence rates when the walk is being pushed towards the surface.

1. Introduction

The introduction of micro-manipulation techniques such as atomic force microscopy (AFM) and optical tweezers [8, 21] has led to an interest in the theoretical description of polymer molecules subject to a force. If we are interested in linear polymers then the natural model is a self-avoiding walk [5, 16]. Consider the d -dimensional hypercubic lattice, Z^d , and attach the obvious coordinate system (x_1, x_2, \dots, x_d) so that each vertex of the lattice has integer coordinates. If we are interested in polymers interacting with a surface we can take the hyperplane $x_d = 0$ as the relevant surface and consider self-avoiding walks starting at the origin and with no vertices having negative x_d -coordinate. These are called *positive walks*.

Suppose that $c_n^+(v, h)$ is the number of n -edge positive walks with $v + 1$ vertices in $x_d = 0$ and with the x_d -coordinate of their last vertex equal to h . Define the partition function as

$$C_n^+(a, y) = \sum_{v, h} c_n^+(v, h) a^v y^h \quad (1)$$

where $a = e^{-\epsilon/kT}$ and $y = e^{f/kT}$. ϵ is the energy associated with a vertex in the surface, f is the applied force, k is Boltzmann's constant and T is the absolute temperature. This is a model for polymers interacting with the surface so that the polymer can be adsorbed, with a force applied normal to the surface to pull the polymer off the surface. There are some rigorous results about this problem [4, 13] (see section 9.7 in reference [14]), as well as several numerical studies either by Monte Carlo methods [15] or by exact enumeration and series analysis [4, 17]. See [9, 18, 19] for related work.

The problem has independent interest if $a = 1$ so that there is no interaction with the surface (except that the surface is impenetrable) [1, 12]. In particular Beaton [1] has shown that the walk is ballistic for any $f > 0$. See also [9]. There are some results about the related problem of polygons pulled away from a surface as a model of ring polymers [10, 11],

Figure 1. (a) A positive walk pulled at its endpoint in the vertical direction from a surface. (b) A positive walk pulled at its highest vertices in the vertical direction.

In the treatments of self-avoiding walks described above [1, 4, 13, 15, 17] the force is applied at the last vertex of the walk, as in figure 1(a). What happens if the force is applied in some other way? In an AFM experiment the monomer in contact with the tip will not always be the last monomer in the polymer and it is interesting to enquire how robust the results are. In a recent paper [3] the force is applied differently. Their idea is to apply the force in the plane containing the vertices of the walk that are furthest from the surface (see figure 1(b)). Suppose that $c_n(v, s)$ is the

number of n -edge positive walks with $v + 1$ vertices in the surface and with span in the x_d -direction equal to s . The corresponding partition function is

$$C_n(a, y) = \sum_{v, s} c_n(v, s) a^v y^s \quad (2)$$

When $a = 1$ (no surface attraction) the problem has been considered in [3, 12].

Instead of pulling a walk away from the surface one can push the walk towards the surface ($f < 0$ or $y < 1$) [3, 12]. Having the force applied at the last vertex or in the confining plane seems then to be very different and, for small n , this is apparent from Monte Carlo data [12]. In [3] the authors consider the finite n behaviour in the latter case and they find unexpected subdominant correction terms. These are probably not present in the first case (with the force applied at the last vertex) [3, 4]. In this paper we compare and contrast the behaviour with these two ways of applying the force. We consider both pushing the walk towards the surface ($y < 1$) and pulling away from the surface ($y > 1$).

2. Bridges subject to a force

We shall be concerned with the situation where there is no attractive interaction with the surface. We define the two generating functions

$$C^+(y, z) = \sum_n C_n^+(1, y) z^n, \quad C(y, z) = \sum_n C_n(1, y) z^n. \quad (3)$$

We define a *bridge* as a positive walk with the extra conditions that

- (i) the first edge is in the x_d -direction, and the walk does not return to the hyperplane $x_d = 0$;
- (ii) the x_d -coordinate of the last vertex is at least as large as that of any other vertex.

Let $b_n(h)$ be the number of n -edge bridges with the x_d -coordinate of the last vertex being h . Define the generating function

$$B(y, z) = \sum_{h, n} b_n(h) y^h z^n. \quad (4)$$

Define the slab S_w to be the set of lattice vertices with x_d -coordinate satisfying $0 \leq x_d \leq w$. Define the generating function of bridges that span S_w as

$$B_w(z) = \sum_{n=w}^{\infty} b_n(w) z^n. \quad (5)$$

Lemma 1. $B_w(z)$ is singular at $z = z_w$ where $z_w \geq z_{w+1} \geq 1/\mu$ and $\inf_w z_w = 1/\mu$.

Proof: If we delete the first edge of a bridge with $n + 1$ edges in a slab with span $w + 1$, translate through unit distance in the negative x_d -direction and decrease the width of the slab by unity we obtain a walk with n edges in a slab of width w . Clearly $b_{n+1}(w + 1) \leq c_n(1, w)$. Consider positive walks with n edges confined to a slab of width w . Unfold each walk in the x_1 -direction [6]. At most $e^{O(\sqrt{n})}$ walks give rise to the same unfolded walk [6]. Suppose that the last vertex of the unfolded walk has x_d -coordinate equal to $w - q + 1$. Add an edge in the positive x_1 -direction and then add $q - 1$ edges in the positive x_d -direction so that the final vertex is in $x_d = w$. Convert this to a bridge with span $w + 1$, unfolded in the x_1 -direction, with $n + q + 1$ edges by adding an additional edge at the beginning of the walk. Therefore $c_n(1, w) \leq b_{n+q+1}(w + 1) e^{O(\sqrt{n})}$. These two inequalities

imply that the free energy of bridges in a slab of width $w + 1$ is equal to that of walks in a slab of width w . Since it is known that the free energy of walks is strictly increasing in w and its limit is $\log \mu$ [7] this proves the lemma. \square

Theorem 1. *The radius of convergence, $z_c^B(y)$, of $B(y, z)$ is equal to $1/\mu$ for all $y \leq 1$, where μ is the growth constant of self-avoiding walks.*

Proof: Since $b_n(h) \leq c_n^+(h)$ it is clear that $B(y, z) \leq C^+(y, z)$. We know that the radius of convergence of $C^+(y, z)$ is $z_c^+(y) = 1/\mu$ for $y \leq 1$ [13] where μ is the growth constant of self-avoiding walks. Hence the radius of convergence of bridges, $z_c^B(y)$ is bounded by

$$z_c^B(y) \geq z_c^+(y) = 1/\mu, \quad \forall y \leq 1. \quad (6)$$

Now

$$B(y, z) = \sum_n \sum_w b_n(w) y^w z^n \geq y^w \sum_{n=w}^{\infty} b_n(w) z^n = y^w B_w(z) \quad (7)$$

for any $w > 0$ and $y \leq 1$. Hence $z_c^B(y) \leq z_w$ for all w and

$$z_c^B(y) \leq \inf_w z_w = 1/\mu \quad (8)$$

for all $y \leq 1$. Hence $z_c^B = 1/\mu$ for all $y \leq 1$. \square

3. Self-avoiding walks subject to a force

We now turn to the problem of positive walks confined between two parallel planes with the planes being pushed together. The following Theorem follows easily from Theorem 1.

Theorem 2. *The radius of convergence, $z_c(y)$, of the generating function $C(y, z)$ is equal to $1/\mu$ for all $y \leq 1$.*

Proof: Clearly $C(y, z) \leq C(1, z)$ for all $y \leq 1$ by monotonicity. But $C(1, z)$ is the generating function of positive walks and has radius of convergence equal to $1/\mu$ [20] so the radius of convergence of $C(y, z)$, $z_c(y)$, is bounded by $z_c(y) \geq 1/\mu$ for $y < 1$. By inclusion $C(y, z) \geq B(y, z)$ so $z_c(y) \leq z_c^B(y)$. By Theorem 1 we have $z_c^B(y) = 1/\mu$ for $y \leq 1$ and this proves the Theorem. \square

If the walk is being pulled away from the surface, so that $y > 1$, we have the following theorem.

Theorem 3. *The radii of convergence of the generating functions $C(y, z)$, $C^+(y, z)$ and $B(y, z)$ are all equal when $y \geq 1$.*

Proof: Since every bridge is also a walk counted by $C^+(y, z)$ and by $C(y, z)$ we have $B(y, z) \leq C^+(y, z)$ and $B(y, z) \leq C(y, z)$ by inclusion. All positive walks are counted both by $C^+(y, z)$ and by $C(y, z)$ and the span of a walk is always at least as large as the height of its last vertex ($s \geq h$). Hence, when $y > 1$, each walk receives at least as large a weight in $C(y, z)$ as in $C^+(y, z)$ so $C^+(y, z) \leq C(y, z)$ when $y > 1$. Of course $C^+(1, z) = C(1, z)$. Hence

$$B(y, z) \leq C^+(y, z) \leq C(y, z), \quad y > 1 \quad (9)$$

and therefore their radii of convergence are related by

$$z_c^B(y) \geq z_c^+(y) \geq z_c(y). \quad (10)$$

Each walk counted by $C(y, z)$ can be converted to a bridge by unfolding in the x_d -direction and at most $e^{O(\sqrt{n})}$ such walks give the same bridge [6]. Moreover the span can not decrease in the unfolding operation so, for $y > 1$, $C_n(1, y) \leq e^{O(\sqrt{n})} B_n(y)$. This implies that $z_c(y) \geq z_c^B(y)$. This, together with (10), proves the Theorem. \square

Figure 2. The limiting mean scaled span \hat{s} as a function of $\log y$. The curve is identical for the two modes of pulling illustrated in figure 1. For $y < 1$, $\hat{s} = 0$, and for $y > 1$ it is positive and asymptotic to 1. It is not known that this curve is continuous at $y = 1$.

4. Discussion

The theorems proved in Section 3 establish that the force dependence of the free energy is identical when the walk is pulled or pushed at its last vertex and at the top (confining) plane. In particular, the critical value $y_c = 1$ (see reference [1]) is the same for the two modes of pulling. These theorems are interesting in view of the results in [3] and [12]. In [3] the authors give convincing arguments and numerical evidence that, in two dimensions when $y < 1$, the partition function $C_n(1, y)$ behaves asymptotically as

$$C_n(1, y) \sim \text{const} \times n^{3/16} \exp[-\text{const} \times u^{4/7} n^{3/7}] \mu^n, \quad (11)$$

where $u = -\log y$. The sub-exponential term $e^{n^{3/7}}$ leads to slow convergence to the infinite n behaviour. See for instance [2].

In [12] the free energy as a function of the force is estimated numerically in three dimensions for both modes of force application. The results clearly support the implication of Theorem 3, and the free energies are very similar even for modest values of n . When the walk is being pushed towards the surface ($y < 1$) the numerical results in [12] show that there are large differences in the two free energies for values of n as large as 4000. The numerical results coupled with Theorem 2 imply slow convergence to the limiting free energy when $y < 1$, and this is exactly the prediction of [3] for $d = 2$.

For walks pushed or pulled in their confining plane we can write the average span, scaled by the number of edges, as

$$\frac{\langle s \rangle}{n} = \frac{1}{n} \frac{\sum_s s c_n(s) y^s}{\sum_s c_n(s) y^s} = \frac{1}{n} \frac{\partial \log C_n(1, y)}{\partial \log y} \quad (12)$$

where $c_n(s)$ is the number of n -edge positive walks with span s . Taking the $n \rightarrow \infty$ limit gives

$$\hat{s} = \lim_{n \rightarrow \infty} \frac{\langle s \rangle}{n} = \frac{\partial [\lim_{n \rightarrow \infty} n^{-1} \log C_n(1, y)]}{\partial \log y} \quad (13)$$

where we have used convexity [12] to justify the interchange of the order of the limit and the derivative. When $y < 1$ this limiting reduced span is zero, by Theorem 2, so that the average span $\langle s \rangle = o(n)$ when $y < 1$. When $y > 1$ the function \hat{s} is positive and the y -dependence is sketched in figure 2. Notice that \hat{s} is asymptotic to 1 in the large y limit. It is not known that \hat{s} is continuous at $y = 1$.
